27 **Abstract**

28 The late Palaeozoic buried Finnmark carbonate platform, in the Norwegian Barents Sea, is a
29 depositional system developed under shifting palaeoclimatic and palaeoceanographic conditions.
30 Detailed core analysis from the explorations wells 7128/4-1 and 7128/6-1, combined with 2D seismic
31 sections and data from previous studies in the area have allowed a re-evaluation of the depositional
32 scenarios of the main lithostratigraphic units (Ørn and Isbjørn Formations). Nine lithofacies associations
33 have been described and interpreted in terms of their depositional environments. During the mid-
34 Sakmarian two major changes are observed between the Ørn and Isbjørn Formations: (1) the variation in
35 the type of the carbonate factories and (2) the change in platform morphology. The changes in the types
36 of carbonate factories were controlled by a number of factors and are expressed by changes in biota,
37 facies associations and depositional geometries. The morphological variation has been associated with a
38 change from a distally steepened ramp to a homoclinal ramp. Our results may help to improve the
39 assessment of future evaluations in the Finnmark Platform area, in terms of reservoir properties, which
40 are strictly associated with the depositional styles and their post-depositional modifications.

41

42

43 **Introduction**

44 The growth history of a carbonate depositional system, its facies heterogeneity and internal
45 architecture, strictly depend on the interaction of numerous biological, chemical and physical factors,
46 acting at different temporal and spatial scales (Read, 1985; Tucker, 1990; James, 1997; Wright and

47 Burchette, 1996, 1998; Pomar, 2001; Mutti and Hallock, 2003; Schlager, 2003; Bosence, 2005; Pomar
48 and Kendall, 2007). Decades of research on modern and ancient examples have highlighted how
49 sensitive the carbonate platforms are to these changes and how difficult is to interpret their evolution
50 considering all the above-mentioned interplays. This is particularly true for the deeply buried
51 depositional systems, often strongly altered by the diagenetic/structural overprint, which are, only,
52 “imaged” by indirect methods such the seismic. However seismic data may convey artifacts that could
53 results in the inaccurate imaging of platforms real morphologies. A comprehensive understanding of
54 how carbonate platforms develop and change across consecutive phases of their growing history,
55 represents a crucial achievement when economical interests linked to fossil fuels originate, since
56 carbonate rocks host more than half of the global hydrocarbon productive reserves (Schlumberger
57 market analysis, 2007, www.slb.com/carbonates). In the last three decades, numerous studies led to a
58 significant step forward in the understanding of the Arctic regional geology, associated with the
59 increasing offshore exploration in the area (Stemmerik and Worsley, 1989; Cecchi, 1993; Lønøy, 1988;
60 Beauchamp and Desrochers, 1997; Ehrenberg et al., 1998a; Stemmerik and Worsley, 2005; Worsley,
61 2006; Larssen et al., 2005; Colpaert et al., 2007; Rafaelsen et al., 2008). One of the late Palaeozoic
62 geological domains attracting most of the interests of the oil industry is represented by the Finnmark
63 Platform, a buried depositional system of the southern Norwegian Barents Sea (fig. 1a), developed as
64 part of the Arctic epicontinental shelf (Bugge et al., 1995; Stemmerik, 2000; Larssen et al., 2002;
65 Worsley, 2006) and dominated by carbonate deposition (for ~27.5 Ma) during the Late Carboniferous–
66 Early Permian (Gzhelian-Artinskian) (Stemmerik, 1997; Ehrenberg et al., 1998a; Larssen et al., 2002).
67 Among the Late Palaeozoic deposit of this area, the stratigraphic interval corresponding to the Gipsdalen
68 Group is considered as having a high reservoir potential (Ehrenberg, 2004; Stemmerik and Worsley,
69 2005 and references therein) and has been, in recent years, the object of renewed interest for E&P

70 purposes to assess future possible plays. At the same time, the Finnmark Platform represents a notable
71 example of how the interplay of simultaneous mechanisms of diverse nature, can influence the long-
72 term and large-scale depositional evolution of a carbonate system.

73 The depositional geometries of the Finnmark carbonates were influenced by the preexistent NE-
74 SW fault-controlled rift topography of the underlying Billefjorden Group (Mississippian clastic
75 sediments), affected by the Devonian-Serpukhovian Atlantic rifting (Stemmerik, 2000; Worsley, 2006).
76 Moreover, during the Late Carboniferous-Early Permian, the Arctic shelf development and its sediment
77 accumulation patterns were influenced by the following major climatic-oceanographic changes:

78 i) the northward drifting of the Eurasian plate, from tropical ($\sim 20^\circ$) to temperate ($\sim 45^\circ$) latitudes, with a
79 rate of about 2-3 mm/y (Scotese and McKerrow, 1990; Scotese and Langford, 1995; Golonka and Ford,
80 2000) and persistent dry climatic conditions (Stemmerik, 2000).

81 ii) The presence of the Gondwanan icecaps, whose expansions and retreats phases controlled the
82 cyclicity and magnitude of the sea-level fluctuations (Stemmerik, 2008 and references therein).

83 iii) The stepwise closure of the Eastern European gateway connecting the arctic regions with the warmer
84 tropical Palaeo-Tethys, influencing successive oceanic circulation patterns (Reid et al., 2007 and
85 references therein).

86 On the Finnmark Platform, the most remarkable sedimentary expression of such palaeoclimatic
87 and palaeoceanographic changes took place during the middle Sakmarian and records a major shift in
88 carbonate factories (Steel and Worsley, 1984; Stemmerik, 1997; Ehrenberg et al., 1998a; Larssen et al.,
89 2002). Exploration wells and shallow cores within the proximal Finnmark domain, reveal a shift in
90 carbonate production style and accumulation between two major (2nd order) depositional phases of
91 platform development, represented by the photozoan-dominated (*sensu* James, 1997) sequences of the

92 Gipsdalen Group (Ørn Formation) and the overlying heterozoan carbonates (Stemmerik, 1997;
93 Ehrenberg et al., 1998a; Larssen et al., 2002) of the Bjarmeland Group (Isbjørn Formation).

94 Although several core- and seismic-based studies have been published so far (Cecchi, 1993;
95 Ehrenberg et al., 1998a; Larssen et al., 2002; Colpaert et al., 2007; Rafaelsen et al., 2008), it is still not
96 fully clear how the Finnmark area evolved in terms of change in geometries and how the early Permian
97 climatic/geodynamic scenario influenced changes in sediment accumulation type. Therefore, for this
98 study, we present the first detailed core analysis across the Asselian-Artinskian Ørn and Isbjørn
99 formations of the wells 7128/6-1 and 7128/4-1 (fig. 4), supported by 2D seismic interpretation across the
100 profile of the eastern Finnmark domain, to better assess the long-term platform evolution and its large
101 scale depositional geometries. This work represent a key study for a more precise reservoir facies
102 evaluation and distribution across the potentially commercial stratigraphic interval of the Ørn Formation
103 (Gipsdalen Group), which is particularly important for the definition of future exploration areas on the
104 Finnmark Platform and on other similar settings of the Barents Sea.

108

109 **Geological evolution and lithostratigraphy**

110 During the Late Palaeozoic, the Arctic shelf lied in the northern margin of the Laurentia super Continent
111 (fig. 1a). It was extended from west to east, from the Arctic Canada across the North Greenland,
112 Svalbard and the Barents Sea, to the Arctic Russia (Beauchamp and Desrochers, 1997, Larssen et al.,
113 2002; Stemmerik and Worsley, 2005; Worsley, 2006). In particular, the late Palaeozoic structural style
114 of the Barents Sea domain derives from Caledonian (NE–SW oriented), and in less extent Timanian

115 (NW–SE oriented) orogenic lineaments affecting the Pre-Devonian basement (Gabrielsen, 1990;
116 Gudlaussón et al., 1998; Samuelsen et al., 2003). The late Devonian–early Carboniferous separation of
117 the North America from the Fennoscandian craton resulted in a rift-controlled palaeo-topography and
118 development of extensional tectono-stratigraphic provinces dominated by wide shelves (Finnmark and
119 Bjarmeland Platforms), relatively deep basins (Hammerfest, Nordkapp, Bjørnøya, Tromsø Basins), and
120 isolated structural features (Loppa and Stappen Highs) (Larssen et al., 2002) (fig. 1b).

121 At present, the Late Palaeozoic Finnmark Platform is a buried monocline (gradient of $\sim 2^\circ$ at the top
122 Permian level, Ehrenberg, 2004) grading northward to the rift-controlled Nordkapp (NE side) and
123 Hammerfest (NW side) Basins (fig. 1b). Southward it is delimited by the Norwegian continent (the
124 Fennoscandian craton) by an angular unconformity. The western boundary is defined by the
125 Ringvassøy-Loppa fault complex whereas eastward the platform gently grades toward the Timan-
126 Pechora Basin (Gudlaugsson et al., 1998; Larssen et al., 2002).

127 The sedimentary record of the Finnmark Platform starts from the Early Carboniferous. According to
128 Larssen et al. (2002), its Late Palaeozoic stratigraphic evolution has been associated to four distinct
129 depositional phases, corresponding to four lithostratigraphic units: the Billefjorden, Gipsdalen,
130 Bjarmeland and Tempelfjorden Groups (fig. 2). Starting from the Mississippian (early Viséan), the rift-
131 related basement morphologies of the Finnmark area have been gradually filled by continental to
132 marginal marine siliciclastic of the Billefjorden Group (Soldogg, Tettegras and Blaererot formations,
133 fig. 2), deposited under tropical-humid climatic conditions as testified by the common presence of coaly
134 horizons (Larssen et al., 2002). A regional middle Serpukhovian-earliest Bashkirian uplift-related
135 unconformity, associated with reactivation of the underlying structural lineaments of the basement,
136 separates the Billefjorden Group deposits from the overlying early Bashkirian-early Sakmarian
137 Gipsdalen Group. The onset of the Gipsdalen Group deposition is characterized by a shift in the tectonic

138 style, with a progressive reduction of the tectonic activity and increasing subsidence (Gudlaugsson et al.,
139 1998; Larssen et al., 2002; Worsley, 2006). Moreover, in this phase took place a significant
140 palaeoclimatic transition from tropical humid to overall semi-arid to arid conditions, (Stemmerik et al.,
141 2000; Worsley, 2006) testified by a gradual increase of shallow and basinal evaporitic deposits. Finally,
142 the Gipsdalen Group was deposited under high-frequency (100 k.y.) and amplitude (> 50m) glacio-
143 eustatic sea-level fluctuations reflecting the Gondwanan icecaps activity (Stemmerik et al. 2008, and
144 references therein; Koch and Frank, 2011). The Group comprises three formations reflecting distinct
145 sub-phases of the Finnmark Platform evolution. The basal interval is associated with the deposition of
146 continental clastics of the Ugle Formation followed by a widely recognized Bashkirian-Moscovian
147 transgression associated with tectonic subsidence that led to the deposition of the Falk Formation. The
148 latter marks a stepwise shift to mixed continental to shallow marine siliciclastic and carbonates, and
149 deeper subtidal evaporites (fig. 2) (Larssen et al., 2005). Starting from the Gzhelian, the proximal areas
150 of the Finnmark domain were mostly dominated by peritidal to subtidal photozoan
151 limestones/dolostones and minor sabkha evaporites of the Ørn Formation, with periodic occurrence of
152 transgressive heterozoan carbonates. Silty mudstones, gypsum and halite were deposited in the basinal
153 areas (fig. 2) (Larssen et al., 2005; Stemmerik, 2008). The early Sakmarian marks an important regional
154 transition associated with a major melting phase of the Gondwanan ice (Stemmerik, 2008; Koch and
155 Frank, 2011). This led to the termination of the glacio-eustacy and marked the depositional transition
156 between the Gipsdalen Group and the overlying transgressive Bjarmeland Group, entirely dominated by
157 heterozoan carbonates.

158 The Bjarmeland Group is characterized by three laterally transitional formations (fig. 2). The shallowest
159 platform environments show crinoidal-bryozoan carbonates of the Isbjørn Formation whereas the deeper
160 distal shelf areas hosted muddy carbonates and shales of the Ulv Formation (Larssen et al., 2002). Outer

161 environments were also site of deposition of large buildups complexes of the Polarrev Formation,
162 dominated by bryozoan-*Tubiphytes* and microbial-stromatactis boundstones (Blendinger et al., 1997;
163 Stemmerik, 1997).

164 From the early Kungurian?-Tatarian?, further northward drifting and cooling, associated with drowning
165 and termination of the temperate carbonate factory on the shelves areas of the Barents Sea, led to the
166 deposition of the outer platform silica- and clastic-dominated Tempelfjorden Group (fig. 2) (Stemmerik,
167 1997; Beauchamp and Desrochers, 1997; Ehrenberg et al., 1998a; Ehrenberg et al., 2001), composed by
168 the Røye Formation and the Ørret Formation, the latter absent on most of the Finnmark Platform
169 (Larssen et al., 2002).

170

171 **Figure 2 here**

172 -----

173 **MATERIALS AND METHODS**

174 **Stratigraphic Dataset and methods**

175 For this study, we described the late Asselian-late Artinskian stratigraphic intervals cored from the wells
176 7128/6-1 and 7128/4-1 (fig. 4), both placed in the central-eastern area of the Finnmark Platform domain,
177 at a distance of 26.1 km from each other (fig. 1b). The standard core description has been performed at
178 cm- to dm-scale and followed by the semi-quantitative microfacies analysis on 154 thin sections, mainly
179 focused on the identification of the carbonate/clastic textures, biological content and sedimentary
180 structures. The well depth is given in measured meters (MD) below Kelly Bushing.

181 The most complete Upper Palaeozoic stratigraphic archive from the subsurface of the Norwegian
182 Barents Sea has been recovered (472.4m of cores/901m of drilled interval) from the exploration well
183 7128/6-1 (drilled by ConocoPhillips in 1991). It represents the type section for the Ørn Formation (215.3

184 m-thick) and the overlying Isbjørn (89.4 m-thick) and Røye Formation (117.4 m-thick). The 51.7 m-
185 thick sequence recovered from the exploration well 7128/4-1 (Statoil, 1993) covers the late Asselian-
186 early Sakmarian uppermost interval of the Ørn Formation. A precise stratigraphic correlation between
187 the 7128/4-1 and 7128/6-1 sequences is ensured by the integration of facies analysis, gamma ray log
188 trends and correlative seismic stratigraphic horizons (fig. 3) (Ehrenberg et al., 1998a; Larssen et al.,
189 2002; Colpaert et al., 2007).

190 Ehrenberg et al. (1998a) defined two 2nd-order and seven 3rd-order depositional sequences (S-1 to S-7)
191 through the Late Carboniferous-Permian interval of the well 7128/6-1 according to the terminology of
192 Goldhammer et al. (1991), bounded by major sequence boundaries (SB) and maximum flooding
193 surfaces (MFS) (fig. 3). Nine lithostratigraphic units (L1-L9) have also been defined by Ehrenberg et al.
194 (2000) on the basis of major vertical facies changes. Units L1-L7 are assigned to the Gipsdalen Gp,
195 whereas the units L8 unit L9 respectively to the Bjarmeland and Tempelfjorden Groups (fig. 3).
196 Fusulinid-based biostratigraphy of the well 7128/6-1 suggests a late Gzhelian to early Sakmarian age for
197 the Ørn Formation, and late Sakmarian to late Artinskian age for the Isbjørn Formation (Ehrenberg et
198 al., 2000 and references therein).

199 The studied segment from the well 7128/6-1 has a thickness of 104.6m (1850-1745.4m). It covers the
200 topmost part of the Ørn Formation (15.3m) and the entire overlying Isbjørn Formation (89.4m) (figs. 3,
201 4). The Ørn Formation segment (1850-1834.7m) corresponds to the early Sakmarian uppermost portion
202 of the sequence S-4 of Ehrenberg et al. (1998a) (upper part of the lithostratigraphic unit L-7, fig. 3). The
203 Isbjørn Formation segment (1834.7-1746m) covers the entire late Sakmarian-late Artinskian third-order
204 sequence S-5 of Ehrenberg et al. (1998a) (lithostratigraphic unit L-8). The sequence deepens upward,
205 with the MFS taken at 1813m, and then it shallows up until the boundary with the Tempelfjorden Group
206 (figs. 3, 4).

207 The studied interval (1865.7-1814m) of the well 7128/4-1 covers most of the third-order depositional
208 sequence S-4 of Ehrenberg et al. (1998a) (lithostratigraphic units L6-L7). The sequence marks a
209 deepening-up trend with a maximum flooding surface (MFS) at 1837.7m, followed by shallowing up to
210 the end of the cored interval (figs. 3, 4). For a better understanding of the depositional-sedimentological
211 features of the Finnmark areas, we also used other available Palaeozoic stratigraphic data, including
212 cores from the exploration wells 7228/9-1S (drilled by Norsk Hydro in 1989) and 7229/11-1 (drilled by
213 Shell in 1993), located in a more distal position, and the shallow bore holes 7128/12-U-01, 7129/10-U-
214 01 and 7030/03-U-01 (IKU Petroleum Research, 1987-1988) drilled landward the studied wells, closer
215 to the Norwegian coast (fig. 1b).

216 Figure 3 here

217 -----

218 **Seismic Dataset and Seismic Stratigraphy**

219 The 2D seismic line 213 from the survey ST9715 has been used for seismic interpretation (fig. 10a). The
220 line is 97 km-long and oriented in NE-SW direction, covering a proximal-distal transect of the eastern
221 Finnmark Platform (see figs. 1 and 10 for location). The frequency values of the 2D line range from 20
222 to 50 Hz, with a dominant frequency of 25 Hz. The internal velocities of the carbonate interval range
223 from 4000 to 6000 m/s, therefore the vertical seismic resolution fluctuates between 40 to 60 m
224 (according to the dominant frequency). Seismic vertical scales are given in two-way travel time TWT (in
225 seconds). The seismic-well tie was done by creating synthetic seismograms that allowed identification of
226 main reflectors in the wells 7128/4-1 and 7128/6-1, as summarized in figure 3. Reflector continuity and
227 key stratal terminations have been considered to identify and mark the selected seismic reflectors and to
228 develop a sequence stratigraphic model along the 2D line (fig. 10b-c). Different seismic attributes (i.e.
229 frequency band filter, variance, gradient magnitude) were applied to highlight the stratal terminations

230 and eventual major structural discontinuities. To facilitate comparisons with previous works based on
231 the same dataset, we followed for the interpreted seismic horizons the nomenclature adopted by Colpaert
232 et al. (2007). The Middle Carboniferous Horizon (MCH) marks the boundary between the Billefjorden
233 and the Gipsdalen Groups and reflects the middle Serpukhovian-earliest Bashkirian major uplift and
234 erosional event. The reflector can be well recognized across the platform since it shows evident
235 truncation of the underlying eroded clastic reflectors (fig. 10b-c). MCH delimitates the base of the
236 seismic unit SU1 of Colpaert et al. (2007) (fig. 3). Upwards, the Middle Gzhelian Horizon (MGH) has
237 been traced. It correlates with the top of the depositional sequences S-2 of Ehrenberg et al. (1998a), thus
238 matches the third-order sequence boundary following the Gzhelian highstand and the onset of the Ørn
239 Formation. MGH marks the top of the seismic unit SU1 of Colpaert et al. (2007) (fig. 3). Following
240 upwards, the Upper Asselian Horizon (UAH) has been selected. It correlates with the second-order
241 sequence boundary at the top of the depositional sequence S-3 (fig. 3) and represents the top reflector of
242 the seismic units SU3 of Colpaert et al. (2007). Upwards, the Middle Sakmarian Horizon (MSH) has
243 been marked and corresponds to the boundary between the Ørn and the Isbjørn Formation (Gipsdalen
244 Group-Bjarmeland Group) (fig. 3). It correlates with the third-order sequence boundary at the top of the
245 depositional sequence S-4 and marks the top of the seismic unit SU4. Evident onlap terminations above
246 MSH in the marginal areas reflect the early transgressive character of the Isbjørn Formation on the
247 platform (fig. 10b-c). The last selected reflector corresponds to the Base Kungurian Horizon (BKH)
248 marking the top of the Bjarmeland Group. It correlates with the third-order sequence S-5 of Ehrenberg et
249 al. (1998a) and marks the top of the seismic unit SU5 (fig. 3).

250

251 **RESULTS AND INTERPRETATION**

252 **Core Description and Facies Analysis**

253 The studied cores are dominated by carbonates (limestones and subordinate dolostones), with minor
254 occurrence of calcareous sandstones, calcareous shales and evaporites (fig. 4). Core description and
255 microfacies analysis allowed defining nine lithofacies associations (LA1–LA9), mainly based on
256 lithology, textures, skeletal/non-skeletal components and sedimentary structures. The facies
257 nomenclature follows at large the first description of the two wells given by Ehrenberg et al. (1998a), as
258 well as other facies studies performed in adjacent coeval deposits of the Arctic region, as in the Svalbard
259 and Sverdrup areas (Beauchamp and Desrochers, 1997; Hüneke et al., 2001; Reid et al., 2007; Blomeier
260 et al., 2009, 2011). Major erosive surfaces are always associated through the cores with distinct mm- to
261 cm-thick silty-clayey partings. Here, due to lack of diagnostic sedimentary/diagenetic features, it is often
262 complicated to assess if such surfaces are associated to phases of subaerial exposure and/or submarine
263 erosion/non sedimentation. However, the vertical facies changes allowed detecting meter-scale (up to
264 8m) subtidal to peritidal shallowing-up (SU) and deepening-up (DU) cycles, defined across the Ørn
265 Formation segment of both the wells, as shown in figure 4. Contrarily, across the Isbjørn Formation of
266 the well 7128/6-1 is difficult to identify a precise stacking pattern and record of depositional cyclicity
267 higher than the 3rd order of Ehrenberg et al. (1998). One reason could be that the Isbjørn Formation was
268 mainly deposited within subtidal settings and under low frequency/amplitude sea level fluctuations.
269 Moreover, the original record of depositional cycles given by facies variations (LA8-LA9) has been
270 further obliterated by burial compaction.

271

272 Figure 4 here, full page

273 -----

274 **Lithofacies Associations (LA)**275 **LA1 - Nodular Anhydrite**

276 This lithofacies is characterized by a mosaic of mm-/cm-sized sub-rounded and elongated nodules of
277 anhydrite, referable to the typical “chicken-wire” and “entherolitic” fabrics (Butler, 1970; Ciarapica et
278 al, 1985; Warren, 2006, and references therein), in a mixed dolomitic and fine sandy to silty matrix (fig.
279 5a). In place the nodules are densely packed and surrounded by thin stylonodular seams as probable
280 result of burial compaction. The lack of thin sections did not allow more detailed petrographic
281 characterization. However, from hand lens observation no faunal content has been detected in the
282 matrix. LA1 occurs as a 1.4 m-thick bed in the studied interval of the well 7128/4-1 (fig. 4) and is
283 interpreted as associated to sabkha-dominated supratidal depositional settings.

284

285 **LA2 – Dolomitic Mudstones**

286 The microfacies is characterized by partially to highly dolomitized mudstones to pure fine crystalline
287 dolostone. Scattered mm- to cm-sized anhydrite nodules are visible (fig. 6a) and arranged parallel to the
288 bedding. They show occasionally an “entherolitic-like” fabric and are at times associated with
289 dolomitized mm-thick laminae. Some dm-thick horizons are completely barren and in place alternated
290 with interval characterized by horizontal fenestral-like structures. Sparse fine-grained sub-rounded
291 quartz grains and isolated peloids of possible microbial origin are common, together with cm-sized chert
292 nodules of diagenetic origin. Faunal content is rare and is made of thin-shelled ostracods and small
293 encrusting foraminifera. This lithofacies caps at times the SU cycles of the 7128/4-1 core (at 1858.9,
294 1853.7 and 1840.5m, fig. 4) and it occurs frequently across the middle Gzhelian and middle Asselian
295 intervals of the well 7128/6-1, associated to the third-order SBs of the sequences S-2 and S-3 of
296 Ehrenberg et al. (1998a) (fig. 3). LA2 is interpreted as deposited in a restricted intertidal hypersaline
297 environment, associated with marginal marine tidal flat/lagoonal settings.

298

299 **LA3 – Fine-grained calcareous Sandstones**

300 This microfacies (fig. 6b) consists of fine-grained, sub-angular to sub-rounded, moderately- to poor-
301 packed and well-sorted quartzose sandstone, including a lesser amount (up to 30 %) of bioclastic
302 fragments of diverse nature, at times completely recrystallized. The intergranular pore spaces are
303 partially occluded by blocky calcite and minor anhydrite cement. The bioclastic content shows
304 fragments of rugose corals, bryozoans and green algae; rare small foraminifera, calcispheres and
305 ostracods are also observed. Non-skeletal grains are represented by rare microbial peloids and muddy
306 lithoclasts. LA3 has a limited occurrence within the studied Ørn Formation interval of both the wells.
307 Two 1.5 and 1.1 m-thick beds have been recognized in the lower and upper part of the 7128/6-1 core
308 (respectively at 1945.5 and 1937.2m, fig. 4). A 0.7 m-thick bed occurs at the top of the core 7128/4-1
309 (1814.7m, fig. 4) (the top of this bed is undefined due to lack of cores upwards). The bedding shows
310 poor-marked parallel to low angle planar cross-laminae, massive horizons and pseudo-bedding due to
311 stylonodular seams of burial origin. LA3 is vertically alternated with bioclastic grainstones (LA5) and
312 has been interpreted as deposited in a sand flat/beach environment, ranging intertidal to shallow subtidal
313 settings, above the FWWB. According to Ehrenberg et al., (1998a), these fine-grained clastics record
314 transport from the land during shoreline progradational phases. Successive washing and sorting by the
315 waves and currents action helped the mixing with shoal/lagoonal-derived skeletal and the removal of
316 the muddy component.

317

318 **LA4 – Bioclastic Wackestone-Packstones**

319 The microfacies shows massive beds of wackestone to packstone textures with moderate to high faunal
320 diversity in a micritic/microsparitic matrix, in place partially to highly dolomitized or with a clotted
321 fabric. The most common taxa are represented by small foraminifera and calcareous algae (fig. 6c-d).

322 The foraminifera refer to globular encrusting and benthic forms as tuberitinids, globivalvulinids,
323 apterinellids, as well as *Tetrataxis* sp., textulariids and bradyinids. Larger fusulinids are less frequent.
324 The calcareous algae are mainly represented by epistamoporids (*Epimastopora* sp.) and minor
325 beresellids. Common subordinate bioclastic variety includes fragments of rugose corals, *Palaeoaplysina*,
326 incrustations of the microproblematica *Tubiphytes* sp., *Girvanella* sp. and *Ellesmerella* sp., red algae
327 (*Komia* sp.), bryozoans, crinoids, ostracods and rare calcispheres. Non-skeletal grains are represented by
328 peloids and rare oncoids. Fine-grained quartz grains are common. This lithofacies occurs frequently in
329 the Ørn Formation interval of both the cores (fig. 4).

330 LA4 is interpreted as deposited in subtidal (below the FWWB) and partially protected lagoonal settings
331 as shown by the presence of mud and the associated high faunal diversity. Such environment was strictly
332 interconnected with sand shoals (LA5) and skeletal buildups (LA6).

333

334 **LA5 – Bioclastic Grainstones**

335 The microfacies is made of fine to coarse grainstones that appear in core poorly to highly cemented,
336 either massive or showing slightly inclined bedding within few horizons. The microfacies is
337 characterized by moderate to highly diversified biota, often fragmented and recrystallized. It is
338 comparable with LA4 as relative abundance among the different taxa. It is mainly composed of smaller
339 foraminifera (encrusting and small benthic forms), fragments of green algae (*Epimastopora* sp.),
340 *Palaeoaplysina*, rugose corals and bryozoans, encrustations of *Tubiphytes* sp., *Girvanella* sp. and
341 *Ellesmerella* sp. Subordinate are red algae (*Komia* sp.), calcispheres, monoaxon sponge spicules and
342 crinoidal fragments. Non-skeletal grains are represented by peloids and rare oncoids (fig. 6e-f). LA5
343 occurs frequently across the Ørn Formation of both the studied cores (fig. 4).

344 LA5 is interpreted as a shoal-dominated shallow subtidal environment, placed around the FWWB and
345 dominated by high hydrodynamic regime that contributed to wash away the muddy sediments through a
346 constant wave action. The clear similarity in the overall skeletal content, plus the frequent vertical
347 transition between LA5, LA4 and the buildup facies of LA6, suggests a strong depositional interaction
348 between these facies. Therefore, we assume that the LA5 represent the reworking of both the muddy
349 lagoonal textures (LA4) and the biostrome debris (see LA6).

350

351 **LA6 – Skeletal Boundstones**

352 It is considered as a composite lithofacies association comprising dm- to m-thick boundstones,
353 dominated by different categories of reef-builders. They are mainly made by *Palaeoaplysina* grains
354 (LA6a) and rugose colonial corals (LA6b), associated with minor phylloid algae (fig. 4). Rare are
355 bryozoans and tabulate corals colonies. LA6 occurs within both the sections and is named following
356 Ehrenberg et al. (1998a).

357

358 **LA6a – Palaeoaplysina Boundstones**

359 The facies is made of mm-thick slightly undulated plates of *Palaeoaplysina*, mostly horizontal and
360 occasionally inclined up to 30°, forming a skeletal framework that baffles/traps sediments. The
361 interstitial space (fig. 6b) is generally made of subtidal wackestone-packstones (LA4), at times
362 dolomitized and occasionally alternated with bioclastic grainstones (LA5), suggesting variations of the
363 hydrodynamic regime associated with the buildup growth. In some cases, the internal structures of
364 *Palaeoaplysina* are often almost completely reset by diagenetic overprint related to meteoric leaching,
365 insomuch that it is difficult to discriminate primary textures. *Palaeoaplysina*-boundstones (figs. 5b, 7a)
366 reach a thickness of about 2m in the 7128/4-1 core. They do not occur within the studied segment of the

367 well 7128/6-1 but are recurrent (and up to 6.7 m-thick) through the underlying Gzhelian-Asselian
368 interval, making most of the lithostratigraphic unit L-4 of Ehrenberg et al. (1998a, fig. 3).

369 *Palaeoaplysina* was a major reef-builder of the Late Carboniferous-Early Permian (Wahlman, 2002;
370 Nakazawa et al., 2011). Its taxonomic affinity is still under debate and so far has been ascribed to
371 sponges (Krotov, 1888; Flügel, 2004), stromatoporoids (Stuckenber, 1895), hydrozoans (Davies, 1971)
372 and green algae. The latest affinity (Vachard and Kabanov, 2007) considers *Palaeoaplysina* as
373 Archaeolithophyllacean red algae.

374 Outcrop analogs of Late Carboniferous-Early Permian *Palaeoaplysina*-dominated buildups have been
375 widely described across the entire northern Pangaea margin (Skaug et al., 1982; Breuninger et al., 1989;
376 Beauchamp and Desrochers, 1997; Stemmerik et al., 1994, 1999; Morin et al., 1994; Bugge et al., 1995;
377 Hüneke et al., 2001; Wahlman, 2002; Stemmerik, 2003; Reid et al., 2007; Blomeier et al., 2011). These
378 works describe such bio-constructions as having different size, morphology and subordinate faunal
379 associations, depending on the interactions between depositional and tectono-stratigraphic settings in
380 which they were growing (Wahlman, 2002; Stemmerik, 2003). This could suggest that the growth of
381 *Palaeoaplysina* was not tied to specific environmental conditions. However, the composition of the
382 subordinate faunal associations (mostly light-dependent organisms) always limits the development to the
383 shallow photic zone. In fact, it has been generally assumed that the growth of m-thick (up to 10m)
384 isolated patches and lenticular laterally-developed banks (up to 100s m-wide) was favored by the
385 reduced accommodation within inner platform environments. In turn, stacked and thicker complexes
386 could have been formed in deeper subtidal settings but always within the photic zone (see Wahlman,
387 2002 for a review). It has been also suggested that, although *Palaeoaplysina* communities did not
388 “despise” agitated conditions (see also Breuninger et al., 1989 and Davies, 1989), they likely preferred
389 to colonize the substrate of more open subtidal settings of the inner/middle ramp areas (Hüneke et al.

390 2001). *Palaeoaplysina* boundstones are interpreted here as forming isolated banks, growing within inner
391 to middle ramp settings. The dominance of interstitial muddy textures (L4-like) suggests buildups
392 development below the FWFB under moderate hydrodynamic settings, with periodic enhanced water
393 dynamism testified by the interstitial grainstones.

394 Occasionally, platy and cup-shaped recrystallized *Eugonophyllum* phylloid algal fragments (Udoteacean
395 and Halimedacean algal affinity; see Forsythe et al., 2002 and reference therein) occupy interstitial
396 cavities among the *Palaeoaplysina* plates, suggesting the presence of colonies in nearby areas. Phylloid
397 algae are not common within the studied intervals but are frequently associated with *Palaeoaplysina* in
398 the lower part of the unit L-4 of the well 7128/6-1, dominated by buildups (fig. 3). *Eugonophyllum*
399 phylloid algae represent widespread tropical-subtropical reef-builder organisms across the Moscovian-
400 Sakmarian time (Wahlman, 2002). In general, the size, morphology and associated fauna of such bio-
401 constructions do not differ from the *Palaeoaplysina*-dominated ones. Therefore, their development has
402 been frequently described within analogous or transitional environmental settings (Bugge et al., 1995;
403 Ehrenberg et al., 1998a; Morin et al., 1994; Stemmerik et al., 1999; Hüneke et al., 2001; Wahlman,
404 2002; Stemmerik, 2003; Nagazawa et al., 2011). Among the two, the more fragile structure (faster
405 growing mode) of the *Eugonophyllum* colonies could have made them preferring quieter (more
406 protected or deeper) environments to colonize the sea bottom (Morin et al., 1994 and references therein).

407

408 **LA6b – Coral/Bryozoan Boundstones**

409 Coral boundstones are present in the Ørn Formation interval of both the studied sections. Differently
410 from the *Palaeoaplysina*-phylloid algal boundstones, their occurrence across the Gzhelian-Asselian L-4
411 Unit of the well 7128/6-1 is limited (Ehrenberg et al., 1998a; Larssen et al., 2002). In the studied
412 intervals, they are arranged in massive cerioid (fig. 5c) or phaceloid (fasciculate structure of separated

413 circular corallites, fig. 5d) colonies of rugose and rare tabulate (syringoporid) corals, reaching up to
414 1.6m. The inter-corallite spaces (fig. 6h) are mostly occupied by coarse-grained packstones-grainstones
415 of LA4 and LA5, with a very variable fauna but prevalence of broken bio-eroded coral fragments,
416 smaller encrusting foraminifera, *Tubiphytes* sp., *Girvanella* sp., *Ellesmerella* sp., bryozoan fragments
417 and micropeloids. Sometimes, intra-corallite dissolution vugs are filled by chert and anhydrite cements.
418 In the studied intervals, the rugose coral colonies are commonly overlain by subtidal muddy facies (LA4
419 and LA7) and occupy the top of the SU cycles. In fact, compared with the *Palaeoaplysina* boundstones,
420 these small patches seemed to have been subjected to greater or at least more constant hydrodynamic
421 regimes which could have been responsible for a more efficient mud removal from interstitial cavities.
422 Therefore, the coral boundstones are interpreted as forming small scattered isolated patches of colonies
423 thriving in a shallow subtidal inner ramp environment.

424

425 **LA7 – Fusulinid Wackestone-Packstones**

426 This lithofacies is made of wackestone-packstones and sporadically packstone-grainstones with
427 moderate faunal diversity and prevalence of fusulinids foraminifera (fig. 7c-d). The bedding style range
428 from massive to nodular (with increase of the fusulinid shelliness usually associated to horizons showing
429 greater burial compaction) and some horizons show a preferred orientation of the biotic components,
430 possibly related to transport by subtidal current. Subordinate skeletal content is often fragmented and
431 shows common small benthic foraminifera (mainly *Tetrataxis* sp.), bryozoans and crinoids. Minor
432 component are represented by *Palaeoaplysina* grains, rugose corals, *Tubiphytes* sp. and brachiopods.
433 *?Eugonophyllum* fragments, trilobites and monoaxon sponge spicules are rarely observed (plate 2c-d).
434 The matrix is occasionally dolomitized and appears as micritic to microsparitic to pseudosparitic,
435 including common silty-grained quartz and glauconite. Lithofacies LA7 occurs sporadically at the base

436 of the SU cycles within both the studied cores (fig. 4). LA7 is interpreted as deposited in a subtidal open
437 middle ramp environment, below the FWWB.

438

439 **LA8 – Crinoidal-Bryozoan Grainstones**

440 The lithofacies shows massive beds of fine to coarse-grained bioclastic grainstones and sporadically
441 rudstones with a low to moderate faunal diversity, dominated by fragments of bryozoans (mostly
442 cystoporid) and crinoids (fig. 7e-f). Secondary skeletal content comprises variable proportions of
443 brachiopods, fusulinids, siliceous sponges (entire and disarticulated in monoaxon spicules) and
444 *Tubiphytes* sp.. Rare small foraminifera, ostracods and trilobites fragments are found, as well as sparse
445 glauconitic mm-sized grains. High-amplitude stylolites and other pressure-solution features are
446 frequently observed on core, together with sporadic cm- to dm-sized roundish chert nodules. This LA
447 occurs in the upper part of the 7128/4-1 Ørn Formation (the interval between 1834m and 1821m) and
448 dominates, together with LA9, the overlying Isbjørn Formation of the 7128/6-1 core (fig. 4). The LA8
449 grainstones were likely deposited in subtidal open marine settings, above and/or around the SWB (distal
450 middle ramp). The dominant fabric of reworked and disarticulated skeletal, point out toward areas
451 characterized by open circulation, affected by currents and storms that possibly contributed to
452 accumulate mud-free bioclastic debris.

453

454 **LA9 – Crinoidal-Bryozoan silty Wackestone-Packstones**

455 This lithofacies is characterized by nodular bioclastic wackestone-packstones and rarely floatstones,
456 bioturbated, dominated by disarticulated crinoids and bryozoans (figs. 5f, 7g-h). The matrix is micritic to
457 calcisiltitic and becomes silty/clayey-rich within the most nodular intervals, showing irregular
458 proportions of very fine sub-rounded quartz grains and less micas, plus mm- to cm-sized glauconitic

459 grains. Subordinate faunal content is represented by variable proportions of brachiopods, monoaxon
 460 sponge spicules, mollusk fragments and rare *Tubiphytes* sp. and fusulinid foraminifera. The nodular
 461 aspect of LA9 is given by the ubiquitous presence of compaction and burial dissolution. This process
 462 favored the accumulation of silty-clayey-dominated horizons following carbonate dissolution
 463 (Ehrenberg, 2004). This lithofacies association is gradually to sharply alternated with LA8 in the upper
 464 part of the 7128/4-1 core and across the entire Isbjørn Formation of the 7128/6-1 core (fig. 4). LA9
 465 represents the transition towards the basin of the LA8 grainstones and is interpreted as deposited within
 466 subtidal open marine outer ramp settings (below the SWB). The chaotic fabric of some horizons might
 467 reflect reworking and accumulation under storm conditions within the proximal outer ramp areas,
 468 whereas in the more distal outer ramp, the size and amount of the bioclastic fragments decreases and
 469 wackestones prevail on packstones.

470

471 Figures 5, 6 and 7 here. Figures 6, 7 full page.

472

473 **Well 7128/4-1 Section**

474 The studied interval of the 7128/4-1 well section is organised in eleven m-scale subtidal to peritidal
 475 cycles. The lower 12.7m (1865.7-1853m) of the section comprise the first 4 depositional cycles and
 476 show regular alternation of bioclastic grainstones (LA5), bioclastic wackestones-packstones (LA4) and
 477 foraminiferal wackestones (LA6), capped at the cycle tops by dolomitic mudstones (LA2). Upwards
 478 (until 1843m) the next two cycles comprise bioclastic grainstones (LA5) and bioclastic wackestones-
 479 packstones (LA4) overlain at the cycle tops by skeletal boundstones (LA6). From 1843m to 1839.1m
 480 bioclastic wackestones-packstones (LA4) are overlain by nodular anhydrite (LA1) whereas in the next
 481 cycle (up to 1833m) bioclastic grainstones (LA5) are alternated with foraminiferal wackestones (LA7)

482 and skeletal boundstones (LA6), followed by the deepening-up segment represented by crinoidal-
483 bryozoan nodular packstone-wackestones (LA9). In the next cycle the LA comprise crinoidal-bryozoan
484 grainstones (LA8), bioclastic wackestones-packstones and grainstones (LA4-LA5) and *Palaeoaplysina*-
485 phylloid algae boundstones (LA6). These LAs are followed by nodular dark calcareous clay-siltstones
486 that represent the deepening-up segment and mark the 3rd order MFS of the sequence S-4 of Ehrenberg
487 et al. (1998a) (figs. 3, 4). Upward the LA shallow-up again; crinoidal-bryozoan silty wackestone-
488 packstones (LA9) are followed by crinoidal-bryozoan grainstones (LA8) and bioclastic grainstones
489 (LA5). The last cycle (1820.4-1814m) is again dominated by bioclastic wackestones-packstones (LA4),
490 shoaling-up to bioclastic grainstones (LA5) and alternated with two skeletal boundstones
491 *Palaeoaplysina*-dominated beds (LA6). At its top the last cycle shows 70cm of calcareous sandstones
492 (LA3).

493

494 **Well 7128/6-1 Section**

495 The studied interval of the 7128/6-1 well section assigned to the Ørn Formation is organised in 5, m-
496 scale, subtidal to peritidal cycles. The first cycle shows bioclastic packstones (LA4) followed by about
497 1.5m of calcareous sandstones (LA3) that can be correlated with the sandstones bed at the top of the
498 7128/4-1 section (Ehrenberg et al., 1998a, fig. 4). Above the cycle deeps-up, as the sandstones are
499 overlain by bioclastic packstones (LA4) and fusulinid wackestone-packstones. The following two cycles
500 (from 1847.5m to 1839.3m) are dominated by foraminiferal wackestones-packstones (LA7) and
501 bioclastic grainstones (LA5), overlain at the cycles top by skeletal boundstones (LA6). The last two SU
502 cycles are represented by bioclastic grainstones (LA4); calcareous sandstones (LA3) cap the top of the
503 first cycle.

504 The shift to the Isbjørn Formation (at 1834.7m) is associated with an erosional surface at the top of the
505 bioclastic grainstones (fig. 5e), followed by about 5 cm of nodular silt that pass upward to massive
506 crinoidal-bryozoan grainstones (LA8). This level corresponds to the 3rd order SB of the sequence S-4 of
507 Ehrenberg et al. (1998a) (fig. 3). The interval (1834.7m to 1746m of the well 7128/6-1) is dominated by
508 an alternation of crinoidal-bryozoan grainstones (LA8) and subordinate nodular crinoidal-bryozoan
509 wackestone-packstones (LA9). The first 4.5m show massive grainstones (LA8). Upwards, the nodular
510 LA9 prevails on LA8, showing an overall deepening trend up to 1813m. Here, a 70 cm-thick calcareous
511 shaly wackestone bed marks the MFS of the sequence S-5 of Ehrenberg et al. (1998a) (fig. 4). Upwards,
512 the section is dominated until the top by grainstones (LA8) with sporadic occurrence of nodular
513 wackestone-packstones (LA9). In the topmost 20cm of the section, nodular packstones show centimetric
514 bioturbation cavities filled by micro-breccia, in a matrix of greenish silt. The last 10cm are completely
515 brecciated and capped above an erosional contact by the overlying calcareous shales of the
516 Tempelfjorden Group.

517 The presence of an early-middle Sakmarian stratigraphic hiatus marking the boundary between the
518 Gipsdalen and Bjarmeland Groups is observed at regional scale, affecting with a slight different
519 temporal occurrence structural highs and most of the proximal depositional areas of the Arctic domain
520 (Stemmerik and Worsley, 2005 and references therein). However, the duration of such gap seems to
521 reflect local settings. It is associated with karst features in Spitsbergen, Bjørnøya and North Greenland
522 (Stemmerik et al., 1996, 1997; Worsley et al., 2001; Stemmerik and Worsley, 2005), whereas the
523 corresponding erosional surfaces from the wells 7128/6-1 and 7129/10-U-02 (IKU shallow core) of the
524 Finnmark Platform (fig. 1 b) are devoid of evidences of subaerial exposure (Bugge et al., 1995;
525 Ehrenberg et al., 1998a) and may correspond to a relatively short period of non deposition and
526 submarine erosion prior to the following major transgression. As stated also by Groves and Wahlman

527 (1997), the carbonate succession from the core 7128/6-1 was characterized by cyclic hiatuses, which are
528 below the resolution of the fusulinid-based biostratigraphy.

529

530 **DISCUSSION**

531 **Carbonate factories and depositional palaeoenvironments**

532 Following previous classifications (Lees and Buller, 1972; Nelson, 1988a, b), Beauchamp (1994)
533 introduced a specific nomenclature for the Palaeozoic biotic/abiotic associations that consider
534 temperature-controlled sediment distributions based on palaeolatitudinal and palaeobathymetric variations
535 (see also Beauchamp and Desrochers, 1997). Such nomenclature includes the following sedimentation
536 modes: Chlorofoam (dominated by calcareous algae and benthic foraminifera), Bryonoderm-extended
537 (dominated bryozoan and echinoderms, plus subordinate Chlorofoam components) and Bryonoderm
538 (dominated by bryozoans, echinoderms, brachiopods and siliceous sponge spicules). In view of the close
539 affinity with the faunal associations found in this study, the Chlorofoam, Bryonoderm-extended and
540 Bryonoderm modes will be used instead of the general warm-, mixed and cool-water sedimentation
541 modes respectively.

542 According to our microfacies analysis, the Asselian-early Sakmarian marine interval of the Ørn
543 Formation records inner to outer ramp deposits (fig. 8a). Diversified associations dominated by small
544 benthic foraminifera, green algae and encrusting communities, thrived in the shallowest, photic, warm
545 inner ramp areas, characterized by intertidal sabkha/tidal flats, subtidal partially protected lagoons,
546 shallow sandbars and m-thick buildup patches dominated by *Palaeoaplysina* and rugose corals. From
547 the middle ramp downward, light-dependent communities are stepwise replaced by a mixed,
548 Bryonoderm-extended fauna. Here, fusulinids and minor *Palaeoaplysina*, rugose and tabulate corals,
549 were associated with typical heterozoan taxa as bryozoans and crinoids (LA7). Finally, the outer ramp

550 domains were dominated by the growth of heterozoan Bryonoderm communities (bryozoans, crinoids,
551 brachiopods).

552 Comparable lateral facies trends have been also observed in the Ørn Formation of the proximal
553 shallow cores 7030/03-U-01 and 7129/10-U-02 (Bugge et al., 1995 and Ehrenberg et al., 2000). In
554 addition, similar variations of the facies patterns with water depth (from photozoan to heterozoan) have
555 been suggested for many other coeval Arctic neritic domains of the Arctic shelf (Kleilen, 1992; Morin et
556 al. 1994; Beauchamp and Desrochers, 1997; Hüneke et al., 2001; Reid et al., 2007; Blomeier et al.,
557 2011).

558 The sedimentary record of the most distal and deepest environments of the Finnmark domain
559 during the deposition of the Ørn Formation is given by cores from the wells 7228/9-1S and 7229/11-1
560 (fig. 1, black circles). They are characterized by transgressive silty nodular mudstones alternated with
561 lowstand subtidal evaporitic sequences. The evaporites are associated with intervals of increased
562 restricted conditions and isolation of the Nordkapp Basin (Larssen et al., 2002; Rafaelsen et al., 2008;
563 Stemmerik, 2008) and possibly correlate, in the well 7128/6-1, with the lithostratigraphic units L-3 and
564 L-5 (dominated by dolomitic mudstones and marked by the major sequence boundaries S-2 and S-3 (fig.
565 3; Ehrenberg et al., 1998a; Colpaert et al., 2007).

566 Starting from the middle Sakmarian, the deposition of the Bjarmeland Group marks a significant
567 change in the sediment accumulation type. The studied cores (fig. 4) from the Isbjørn Formation reveal
568 that the Finnmark became site of deposition of pure heterozoan facies also in the proximal areas,
569 reflecting a landward transition of the Bryonoderm sedimentation mode. According to our facies
570 analysis and previous interpretations of the core 7128/6-1 (Ehrenberg et al., 1998a), the schematic facies
571 model of figure 8b shows a general ramp profile where inner-middle ramp storm influenced areas were
572 occupied by crinoidal-bryozoans grainstones (LA8) and, below the SWB, by the mud-dominated

573 nodular textures of the LA9. The coeval interval (sequence S-5) from the shallow cores 7129/10-U-02
 574 and 7128/12-U-01 is thinner (bout 45m vs. 89.4m in the well 7128/6-1) and dominated by the skeletal
 575 grainstones (similar to our LA8), suggesting shallower conditions, less accommodation and presence of
 576 stratigraphic hiatuses due to lack of biozones (fusulinid zone 20) (Bugge et al., 1995; Ehrenberg et al.,
 577 2000). Seaward, cores from the well 7229/11-1 show that the outer ramp domains were at the same time
 578 site of deposition of hundreds of m-thick stacked buildups made up by bryozoans and *Tubiphytes*
 579 assemblages of the Polarrev Formation (not shown in figure 8b; Blendinger et al., 1997; Stemmerik,
 580 1997; Larssen et al., 2002), forming an evident and mostly continuous ridge easily detectable on seismic
 581 (fig. 9). Deeper silty mudstones of the Ulv Formation were deposited around the buildup belt and
 582 basinward.

586

587 **Factors affecting the shift in carbonate factories**

588 Photozoan vs. heterozoan modern sediments distribution essentially varies with respect to sea-water
 589 temperature and depth, latitude and circulation patterns (Lees and Buller 1972; James 1997; Mutti and
 590 Hallock, 2003) that in turn, also regulate the trophic resources distribution by upwelling across the shelf.
 591 The evolution of the Finnmark Platform as part of the huge shallow Arctic epicontinental shelf was
 592 affected by northward drifting of the Eurasian plate with a rate of 2-3 mm/year (Scotese and McKerrow,
 593 1990; Scotese and Langford, 1995; Golonka and Ford, 2000). During the deposition of the Ørn
 594 Formation (Gzhelian–Sakmarian) the Barents Sea domain was still placed within the (sub-) tropical belt
 595 (20°–30°) and was associated with high frequency (100 k.y.) and amplitude (>50m) glacio-eustatic sea-

596 level variations (Stemmerik, 2008). Moreover, the palaeogeographic scenario suggests open current
597 circulation patterns due to the NW-SE connections between the Panthalassa and the Palaeo-Tethys
598 Oceans, through the Uralian seaway (fig. 1a) (Reid et al., 2007; Blomeier et al., 2009).

599 On the base of these assumptions and considering the sedimentary records of the Sverdrup Basin, the
600 Svalbard archipelago and Easter European Platform, has assumed that the Late Carboniferous-earliest
601 Permian sedimentation patterns across the Arctic domain were influenced by prevalent circulation of
602 wind-driven oligotrophic warm waters at the surface, from both the Tethys and Panthalassa Oceans
603 (Reid et al. 2007). Therefore, the presence of a stable thermocline during the Moscovian-Sakmarian is
604 suggested to explain the widespread development of shallow photozoan biota (associated with
605 supra/intertidal evaporites in the most restricted areas), separated by deeper heterozoan mesotrophic
606 associations within the same depositional systems. Such hypothesis is consistent with our
607 palaeoenvironmental interpretations (fig. 8a) that consider (sub-) tropical latitude and a depth-related
608 transition in carbonate factories across the Ørn Formation sedimentary record of the Finnmark Platform.
609 From the late Sakmarian, the onset of a Bryonoderm sedimentation mode was established on the
610 Finnmark Platform and across the Arctic province (Stemmerik, 1997). Such significant modification in
611 the depositional style is commonly associated to the effect of: i) an early Sakmarian flooding event
612 during a major melting phase of the Gondwanan icecaps (Stemmerik, 1997; Stemmerik et al., 2008 and
613 references therein); ii) the generalized cooling due to further northward drifting of the Arctic shelf up to
614 the temperate latitudinal belt (Stemmerik, 1997); iii) the stepwise closure of the Uralian corridor
615 connecting the tropical Tethyan waters with the Arctic seas (Fokin et al., 2001; Reid et al., 2007 and
616 references therein).

617 The interplay of such mechanisms led to a new climatic-oceanographic Arctic scenario, characterized by
618 temperate and more seasonal climatic conditions associated with a low frequency/amplitude of the sea-

619 level cyclicity and a generalized subtidal open marine storm-affected sedimentation. Such circumstances
620 possibly contributed to weaken the water masses stratification, resulting in a disruption of the
621 thermocline and consequent upwelling and influx of panthalassic nutrient-rich cool waters across the
622 entire Arctic shelf (Beauchamp and Baud, 2002; Reid et al., 2007). The result was the ultimate turnover
623 in favor of heterozoan assemblages that from the late Sakmarian invaded also the more proximal and
624 shallow environments, and dominated them up to the Kungurian time.

625 Besides cooling and upwelling-driven mesotrophic conditions, enhanced nutrients delivery through
626 siliciclastic continental run-off could have been another important factor for the intensification of the
627 trophic levels and the consequent instauration of a full Bryonoderm mode, especially with regard to
628 land-attached carbonate depositional systems as the Finnmark Platform, where clastic input is an
629 ordinary aspect. In the studied sections, but also in the coeval intervals of the shallow cores and in the
630 underlying Gzhelian Ørn Formation (well 7128/6-1), a discrete amount of scattered quartz grains is
631 always present (Bugge et al., 1995; Ehrenberg et al., 1998a); but a considerable relative increase of
632 quartz-dominated very fine sand and silt is observed in the bryozoan-crinoidal wackestone-packstones
633 (LA9) of the Ørn and the Isbjørn Formation. The clastic component within these intervals could likely
634 reflect phases of increased land-derived siliciclastic supply associated with coastline retrogradation
635 (Ehrenberg et al., 2000) and successive reworking due open circulation. However, in our case the
636 observed increasing rate of insoluble detrital load could be an artifact due to burial
637 compaction/dissolution, whose sedimentary features (stylolites and nodular seams) represent a typical
638 aspect of the lithofacies association LA9.

639

640 **The Finnmark Platform large scale geometries**

641 The Finnmark area is affected by the Late Devonian–middle Carboniferous inherited extensional trend
642 (reactivated following the Caledonian structures), striking NE-SW and marking the overall boundary
643 with the Nordkapp Basin (Faleide et al., 1984; Gudlaugsson et al., 1998). Prior to the deposition of the
644 Ørn Formation, syn-rift structural highs were eroded and the depressions partially filled by clastics of
645 the Billefjorden and “lower” Gipsdalen Group (Ugle and Falk Formation). Therefore, following the
646 Moscovian transgression, the onset of the Ørn Formation carbonates on the Finnmark Platform took
647 place in relatively diverse and subsiding neritic settings reflecting local physiography, along with the
648 previous-mentioned climatic and oceanographic changes. This makes not straightforward to assess how
649 the large scale depositional profile of the platform evolved following the biological shift between the
650 Gipsdalen and Bjarmeland Group, and how to classify this system according with the current geometric
651 classifications that vary from rimmed shelves and homoclinal ramps, through a wide number of
652 transitional profiles (Pomar, 2001; Williams et al., 2011). Such complexity is also revealed by the
653 dissimilar hypotheses made by previous authors (on the base of seismic- and/or core analyses) about the
654 development of the platform profile across the Gipsdalen-Bjarmeland transition.

655 For example, Nilsen et al. (1993) considered a major shift from a homoclinal ramp during the
656 deposition of the Gipsdalen Group to a rimmed shelf with marginal buildups during the deposition of
657 Bjarmeland Group, whereas Ehrenberg et al., (1998a) suggested that a ramp profile (with a marginal
658 buildup trend) was already established during the deposition of the Gipsdalen Group”. Later, Colpaert et
659 al. (2007) suggested a shift from a prograding carbonate platform/slope system with marginal buildup
660 complexes during the deposition of the Gipsdalen Group, to a restricted heterozoan platform with
661 stacked buildup complexes on the slope during the deposition of the Bjarmeland Group. Finally,
662 Rafaelsen et al. (2008) suggested that the Finnmark was a “northerly dipping distally steepened ramp
663 with buildups” from the mid Carboniferous throughout the Permian, with detached intra-basinal

664 platforms (structural high on well site 7229/11-1) that became attached to the ramp during the deposition
665 of the transgressive Bjarmeland Group.

666 A generally accepted feature, in all the studies, is represented by an arched-like platform margin active
667 during the deposition of the Gipsdalen Group, revealed by seismic profiles and partially controlled by
668 the inherited NW-SE lineaments. The E-W trend of the margin and its approximate position across the
669 platform (fig. 9a) is given by considering the southern depositional limit of the Gzhelian–Asselian
670 lowstand evaporitic sequences of the Nordkapp Basin, pinching out on the margin itself (Gérard and
671 Buhrig, 1990; Bruce & Toomey 1993; Gudlaugsson et al., 1998; Ehrenberg et al., 1998a; Colpaert et al.,
672 2007). Similarly, the overall distribution of the late Sakmarian–Artinskian heterozoan buildups of the
673 Polarrev Formation (Bjarmeland Group) has been seismically mapped within the Finnmark domain
674 (Gudlaugsson et al., 1998; Ehrenberg et al., 1998a). Their southern limit is mostly placed slightly basin-
675 ward of the Gzhelian–Asselian basinal evaporites and follow nearly the same lineaments along the
676 platform (fig. 9b).

677 On the base of these assumptions, we propose that the key to delineate a reliable development of the
678 Finnmark Platform depositional profile through time, together with the information from the facies
679 analyses, could be given by considering i): the location of the buildups across the platform, their
680 forming-biota and shape variation across the Gipsdalen and Bjarmeland Groups; ii) the position of the
681 margin and its evolution in terms of depth and morphology. These points have certainly a strong
682 implication on assessing the geometry of the Finnmark Platform because, according with the classical
683 models of the carbonate sedimentology, a shallow marginal barrier would point to a more flat-topped
684 platform whereas an offshore deeper margin to a distally steepened ramp profile (Read, 1985; Pomar,
685 2001 and references therein).

686 Previous and current cores analyses from the wells 7128/6-1, 7128/4-1 and shallow cores (Bugge et al.,
687 1995; Ehrenberg et al., 1998a; Ehrenberg et al. 2000) have assessed that the deposition of the Ørn
688 Formation in the proximal platform areas were characterized by presence of scattered (up to 6m) bio-
689 constructions dominated by *Palaeoaplysina*-phylloid algae and subordinate corals. These bodies likely
690 had a tabular and laterally extended (>100 m-wide) morphology, as has been highlighted by multi-
691 attribute analyses in the proximal areas of the 3D cube ST9802 (Colpaert et al., 2007; fig. 1b for
692 location). Cyclic subaerial exposures bounding the buildup bodies in the proximal domains suggest the
693 reduced accommodation space as the main factors limiting their vertical growth, favoring in turn their
694 lateral development (Stemmerik et al., 1999; Colpaert et al., 2007). On the other hand, seismic-scale
695 mounded features within the Ørn Formation have been interpreted as buildups along the marginal
696 domains of platforms and structural highs (Samuelsberg et al., 2003; Colpaert et al., 2007; Rafaelsen et
697 al., 2008), even though a precise assessment of the biota making these buildups is strongly limited by
698 missing cored sequences through the observed mounded features.

699 An example of marginal bioconstructions developing on a seismic scale during the deposition of the
700 Gipsdalen Gp has been shown in the distal part of the 3D seismic cube ST9802 (Colpaert et al. 2007),
701 where Asselian seismic scale mounded structures have been interpreted as transgressive/highstand
702 polygonal buildup complexes (top SU2, Base Asselian Horizon), as well as km-long complex (top SU3,
703 below the UAH) associated to a platform barrier. According to this interpretation, starting from the early
704 Asselian (SU2-SU3 seismic units, see fig. 3) the system evolved as a rimmed platform with a prograding
705 margin and a slope (up to 400 m-high), on which the lowstand basinal evaporites pinched out. Later, on
706 top of the Mid Sakmarian Horizon (MSH), the transgressive sequence corresponding to the lower part of
707 the Bjarmeland Gp (fig. 3) led to retrogradation of the margin and the development of a restricted
708 heterozoan platform with stacked bryozoan-*Tubiphytes* buildup complexes on the slope.

709 In this study, the 2D seismic sequence stratigraphic interpretation of the marginal platform area (fig.
710 10b) shows, similarly to Colpaert et al. (2007), a carbonate system prograding during highstand phases
711 of the third-order depositional sequences S-3 and S-4, bounded by MGH, UAH and MSH. Seismic--
712 scale mounded buildup-like morphologies are also recognized on the margin and the slope areas
713 between MGH and UAH (fig. 10b).

714 With the available data it is not possible to assess the nature of the biotic associations making up the
715 marginal buildups associated with the Ørn Formation, which would mainly depend on the dominant
716 palaeoecological settings favoring certain reef-builders more than others. It has been suggested that also
717 the marginal and distal/deeper buildup assemblages were dominated by *Palaeoaplysina* and phylloid
718 algae associations, assimilated to the outcropping stacked complex observed in the Kapp Dunér
719 Formation in Bjørnøya (Lønøy, 1988; Stemmerik et al., 1994; Stemmerik and Worsley, 2005). However,
720 according with the facies study proposed here, during the deposition of the Ørn Formation the Finnmark
721 offshore environments were characterized by heterozoan assemblages (fig. 8); therefore we cannot
722 exclude that deep bryozoan-*Tubiphytes* buildups/mounds developed on the Finnmark platform also
723 during the Gzhelian-Asselian time, prior to the formation of the facies-equivalent and much thicker
724 (Colpaert et al., 2007; Rafaelsen et al., 2008) overlying complexes of the Bjarmeland Group (described
725 in the distal well 7229/11-1).

726 This possibility is further supported by the light-dependent nature of the *Palaeoaplysina*-phylloid algae
727 buildups and their frequent associated fauna, commonly thriving in the shallowest platform domains
728 (inner to middle ramps). Similarly, a depth-related change in biotic buildups composition at tropical-
729 subtropical latitudes, from the shallow *Palaeoaplysina*-phylloid algae to the deeper bryozoan-dominated
730 buildups has been observed during the Asselian-Sakmarian of the Sverdrup Basin (Beauchamp, 1993;
731 Beauchamp and Desrochers, 1997) and during the early Carboniferous (Moscovian) of the north

732 Greenland (Stemmerik, 2003). In the latter, buildups dominated by bryozoans and associated heterozoan
733 fauna have been placed around the lower limit of the photic zone.

734 Hence, on the base of these assumption and from the large-scale view of the seismic line of fig. 10a, we
735 suggest to consider the eastern Finnmark Platform geometry during the deposition of the Ørn Formation
736 as a wide (>100km) distally steepened ramp (fig. 10a). We believe that the carbonate system was gently
737 grading toward the offshore domains where a subtidal margin/slope system (below the SWB) was
738 associated with the development of seismic scale heterozoan-dominated buildups during transgressive–
739 highstand phases (fig. 10c), favored by accommodation rates (due to the coupled effect of eustacy and
740 subsidence rates) greater than in most of the proximal areas of the platform.

741 Hence, it can be assumed that during the deposition of the Ørn Formation, while the shallowest ramp
742 domains were dominated by peritidal m-scale cycles capped by subaerial exposures and possible
743 formation of structurally-controlled late highstand-lowstand evaporitic deposits (Samuelsberg et al.,
744 2003), the distal depositional areas were mostly sites of subtidal cyclicity and more open circulation.
745 Similarly, Stemmerik (2008) affirms that on the Finnmark domain and during the deposition of the Ørn
746 Formation: “most deposition seems to have taken place in deeper-water, mid- and outer-shelf
747 environments”. In fact, contrarily to what is observed in the proximal domains, the stacked nature of the
748 distal buildups forming seismically recognizable features should clearly point to the presence of a
749 greater available space during transgressive and early highstand phases.

750 Later, with the deposition of the Bjarmeland Gp and the instauration of the Bryonoderm sedimentation
751 mode, heterozoan buildups developed almost across the whole ramp. In the most proximal domains, the
752 presence of heterozoan bio-constructions below the seismic resolution cannot be excluded. However,
753 they have not been observed, nor in the cored intervals of the well 7128/6-1 (fig. 3) neither in the coeval
754 shallow cores (Ehrenberg et al. 2000). In the distal shelf areas close to the margin, composition and

755 shape of the heterozoan buildup complexes of the Polarrev Formation are well known from the well
756 7229/11-1 (Blendinger et al., 1997; Stemmerik, 1997) and from detailed 3D seismic interpretations
757 (Rafaelsen et al. 2008; Colpaert et al. 2007). They are dominated by bryozoan-*Tubiphytes* framestones
758 and stromatactis mud-wackestones forming mounds and ridges of 350–1500 m-wide, more than 27 km-
759 long and up to 325 m-high. Their approximate trend along the Finnmark Platform is shown in figure 9.
760 The seismic interpretation of the line 213, also supported by the interpretation of Colpaert et al. (2007)
761 shows that the heterozoan buildups complexes of the Polarrev Formation developed between MSH and
762 BKH in a slightly distal position with respect to the offshore margin of the underlying prograding
763 distally steepened ramp (see fig. 9). Onlap reflectors on top of MSH are associated with the major
764 transgressive Sakmarian depositional phase of the Bjarmeland Group, causing the stepwise reduction of
765 the pre-existent slope gradient (fig. 10b-c). Therefore, we suggest that the shift to the Bjarmeland Group
766 possibly led to the instauration of a heterozoan-dominated homoclinal ramp, devoid of a clear subtidal
767 margin/slope system and gently grading toward the Nordkapp Basin. Huge heterozoan buildup
768 complexes developed in the outer ramp, growing on the seafloor and along topographic/structural reliefs
769 as isolated mounds and polygonal ridges and supported by optimal ecological conditions, coupled with
770 the available accommodation space created by tectonic subsidence and eustatic sea-level rise. In fact,
771 after the Sakmarian major flooding and according with the current palaeoceanographic/palaeoclimatic
772 scenario, the increased accommodation, lowering of the seawater temperatures and enhanced trophic
773 levels created the best conditions for the heterozoan biota to create the observed mounded belt across the
774 offshore late Sakmarian–late Asselian Finnmark environments (fig. 10b-c).

775

776 **Implications from hydrocarbon perspective**

777 The described interplay between climatic/oceanographic/geodynamic factors across the Upper
778 Carboniferous-Lower Permian and the resulting major biotic turnover and large scale geometries
779 strongly influenced the depositional history of the Finnmark Platform with major influences on the
780 development of potential Palaeozoic plays in the areas. Core-based reservoir models and diagenetic
781 studies (Ehrenberg et al., 1998b; Stemmerik, 1999) from the well 7128/6-1 indicate that the Ørn
782 Formation is characterized by many high (primary and secondary) porosity intervals, given by a
783 combination of different favorable factors as dolomitization and meteoric leaching of the metastable
784 aragonitic skeletons, associated with high amplitude/frequency sea-level fluctuations. Such features led
785 considering the Chloroform shallow domains and the *Palaeoaplysina*-phylloid buildups of the
786 Gipsdalen Gp as the best potential reservoirs of the Barents Sea area (Stemmerik, 1999; Stemmerik and
787 Worsley, 2005). On the other hand, the subtidal Isbjørn Formation carbonates and buildup complexes
788 show very low porosities and are considered non-prospective, due to the overall stable mineralogy of its
789 biotic components (low-Mg calcite) and the common presence of silty-clayey horizons favoring
790 dissolution and calcite cementation through stylolites. Assuming the shelf profile as a distally steepened
791 ramp rather than a flat-topped platform during the deposition of the Ørn Formation, as our data suggest,
792 has dramatic implications for reservoir studies. In fact the lateral extension of the areas affected by
793 subaerial exposure on the shelf (more prone to develop secondary porosity) and therefore more
794 prospective in terms of potential reservoir interval, change drastically according with the two different
795 scenarios. This represents a key point to take in account when planning future exploration in the eastern
796 Finnmark domains and in other buried land-attached Palaeozoic carbonate depositional systems along
797 the Arctic epicontinental shelf.

803 **Conclusions**

- 804 • Facies analysis of the uppermost Ørn Formation from the cores 7128/6-1 and 7128/4-1 of the
805 Finnmark Platform reveals that during the Asselian–early Sakmarian the shallowest inner ramp
806 environments were dominated by a Chlorofoam sedimentation mode and photozoan biota. Such
807 communities were laterally replaced, towards the deeper and distal outer ramp environments, by
808 mixed Bryonoderm-extended and by heterozoan Bryonoderm assemblages. In view of this depth-
809 related transition in carbonate factories, and according with the coeval palaeoceanographic-
810 palaeoclimatic scenario across the Arctic domain (sub-/tropical latitudes of deposition, open
811 connection and current circulation with the Tethyan tropical realm), our results support the
812 hypothesis of the presence of a stratified water column and a thermocline separating the
813 photozoan biota thriving in shallow and warm waters from the heterozoan associations, well
814 adapted to deeper and cooler mesotrophic waters.

- 815
- 816 • The shift from the Ørn to the Isbjørn Formation in the proximal well 7128/6-1 reveals the full
817 instauration of the Bryonoderm sedimentation mode on the Finnmark Platform, starting from the
818 middle-late Sakmarian. Transgressive heterozoan facies invaded also the proximal shallow shelf
819 areas (before occupied by photozoan communities) favoring the installation of an open and
820 storm-dominated ramp. Such modifications of the depositional style in favor of the heterozoan
821 communities were driven by the evolution of climatic-oceanographic Arctic scenario (melting
822 phases of the Gondwanan icecaps, cooling due to drifting to temperate latitudes, closure of the

823 connections with the Tethyan realm) that led to the disruption of the thermocline with
824 consequent influx of nutrient-rich cool waters across the Finnmark domain.

825

826 • Our facies and palaeoenvironmental analysis (supported by 3D seismic interpretations), suggest
827 that during the deposition of the Ørn Formation, *Palaeoaplysina*, phylloid algae and rugose
828 corals were responsible for the formation of m-scale buildup patches within the inner to middle
829 ramp environments, whereas the still unexplored mounded seismic features observed offshore,
830 along the subtidal margin/slope system of the distally steepened ramp, could have been formed
831 by the heterozoan communities, according to the observed depth-related shift from chlorofoam
832 to bryonoderm sedimentation mode. Following the middle Sakmarian transgression and the shift
833 to a heterozoan homoclinal ramp profile, bryozoan-*Tubiphytes* stacked buildup complexes
834 developed along the outer ramp domains.

835

836 • Our seismic interpretation across the eastern platform profile, coupled with facies and
837 palaeoenvironmental analysis, suggests that the eastern Finnmark large scale geometry changed
838 from a distally steepened ramp to homoclinal ramp, following the ongoing climatic-
839 oceanographic modifications and the consequent shift between the two major depositional phases
840 represented by the Gipsdalen and the Bjarmeland Groups. Due to the presence of high
841 frequency/amplitude glacio-eustatic fluctuations, it can be assumed that during the deposition of
842 the Gipsdalen Group the proximal ramp domains were cyclically subaerially exposed, whereas in
843 the outer ramp a subtidal cyclicity was more persistent. At the same time, major phases of
844 restriction and isolation of the Nordkapp Basin led to the deposition of subtidal evaporitic
845 sequences, pinching out on the distally-steepened ramp slope.

846

- 847 • Given the good reservoir properties of the Gzhelian–Sakmarian Gipsdalen Group within the
848 Finnmark depositional domain and the whole Norwegian Barents Sea area, the assessment of
849 changes in the platform depositional profile as suggested in this study, through the observed
850 regional shifts in sedimentation modes, represents a fundamental point to take in account for
851 future exploration purposes, due to the impact it has on the reservoir properties.

1 **Facies and seismic analysis of the Late Carboniferous–Early Permian Finnmark carbonate**
2 **Platform (southern Norwegian Barents Sea): an assessment of the carbonate factories and**
3 **depositional geometries.**

4

5 **Figure captions**

6 **Figure 1.** a) Late Pennsylvanian (Gzhelian stage, 300 Ma) palaeoceanographic map
7 (from <http://cpgeosystems.com/globaltext2.html>) and palaeo-position of the Finnmark Platform domain
8 within the Arctic epicontinental shelf. b) Structural/depositional domains of the Norwegian Barents Sea.
9 The Finnmark Platform, object of this study, is bordered by the Norwegian land to the south and by the
10 Nordkapp Basin to the north. The map shows the position of the four exploration wells reaching the
11 Palaeozoic interval and the three shallow exploration cores mentioned in the text. The position of the
12 selected 2D seismic line ST9715-213 across the NE-SW platform profile (fig. 8) is shown, together with
13 the 3D cube ST9802. HB: Hammerfest Basin; HBS: Harstad Basin; NH: Norsel High; SD: Samson
14 Dome; ND Nordvang Dome. Modified after Samuelsberg et al (2003).

15

16 **Figure 2.** Late Palaeozoic Lithostratigraphic Units of the Southern Norwegian Barents Sea and their
17 relationship across the Finnmark Platform profile (Modified after Larssen et al., 2005). The stratigraphic
18 intervals of the studied wells 7128/6-1 and 7128/4-1 of the Gipsdalen Gp (Ørn Formation) and the
19 Bjarmeland Gp (Isbjørn Formation) are also shown.

20

21 **Figure 3.** Stratigraphic correlation between the wells 7128/6-1 and 7128/4-1 across the Gipsdalen,
22 Bjarmeland and Tempelfjorden Groups. The scheme is based on the integration of GR profiles, 2nd and
23 3rd order (S-1 to S-7) depositional sequences, Lithostratigraphic Units (L1 to L-9 (from Ehrenberg et al.,

24 1998a) and fusulinid-based biostratigraphy (Ehrenberg et al., 2000). Seismic horizons (dashed lines) and
25 related seismic units (SU1–SU6) across the well 7128/6-1 are from Colpaert et al. (2007). MCH: middle
26 Carboniferous Horizon UCH: upper Carboniferous Horizon, MGH: middle Gzhelian Horizon, BAH:
27 base Asselian Horizon, UAH: upper Asselian Horizon, MSH: middle Sakmarian Horizon, BKH: base
28 Kungurian Horizon, BKH: base Tatarian Horizon. The blue-colored horizons are the ones considered for
29 this study (MCH, MGH, UAH, MSH, and BKH) and represented as blue-dashed lines. Dark green
30 segments correspond to the intervals investigated for this study.

31

32 **Figure 4.** Logs showing the main lithological, stratigraphic and sedimentological features of the studied
33 Asselian-Artinskian intervals from the wells 7128/4-1 (log 1) and 7128/6-1 (logs 2 and 3). For an easier
34 overview of the figure, the stratigraphic relationship between the logs is also shown in the small, pink
35 rectangle. Refer to the text for the explanation of the Lithofacies associations (LA) and their
36 evolution/changes through the sections. Textures/lithologies: c: clay; m/e: mudstone/evaporite; w:
37 wackestone; fs: fine sandstone; p: packstone; g: grainstone; b: boundstone.

38

39 **Figure 5.** Core pictures from the Asselian-Artinskian studied interval, of some of the lithofacies
40 associations (LA) described in the text. a) Densely packed mm to cm anhydrite nodules in a
41 dolomitic/silty matrix (LA1) from the Ørn Formation interval of the well 7128/4-1 (1839.5m). b)
42 Particular of *Palaeoaplysina* boundstones (LA6a) from the Ørn Formation interval of the well 7128/4-1
43 (1818.4m). Note the horizontal/mounded arrangement of the *Palaeoaplysina* plates (p) and the muddy
44 matrix (m) occasionally trapped in the interplate space during successive phases of buildup
45 development. Note also the typical protuberances of the *Palaeoaplysina* thallus (arrows, See also the
46 thin section photograph in plate 3a). c) Particular of coral boundstones (LA6b) from the Ørn Formation

47 interval of the well 7128/6-1 (1843.4m). The colony of rugose corals shows a cerioid arrangement of the
48 corallites, forming a massive framework. d) Rugose coral boundstones (LA6b) from the Ørn Formation
49 interval of the well 7128/6-1 (1839.4m). The colony shows a phaceloid growth type of the corallites,
50 surrounded by bioclastic grainstones of the lithofacies association LA5. e) Erosive surface marking the
51 stratigraphic boundary between the Gipsdalen Gp and the Bjarmeland Gp in the well 7128/6-1
52 (1834.7m). Shallow bioclastic grainstones (LA5) of the Ørn Formation, reflecting a Chlorofoam
53 sedimentation mode, are cut by an erosive surface and overlaid by about 5cm of nodular siltstone,
54 passing upward to subtidal crinoidal-bryozoan grainstones (LA8) of the Isbjørn Formation, associated to
55 a Bryonoderm sedimentation mode. See the text for further explanation.

56 f) Outer ramp crinoidal-bryozoan silty wackestone-packstones (LA9) from the Isbjørn Formation
57 interval of the well 7128/6-1 (1813.8m). The pseudo-nodular aspect of this LA is mostly due to the
58 dissolution of the calcareous component during burial compaction, associated with high silt/clay content.

59

60 **Figure 6.** Thin sections photographs of the most representative lithofacies associations (LA).

61 a) Dolomitized mudstones (LA2) from the Ørn Formation interval of the well 7128/4-1 (1853m). The
62 microfacies shows mm-sized cavities possibly related to intertidal fenestrae or birdseyes, filled by
63 anhydrite cement in a fine dolomitic/micritic matrix, with high intercrystalline porosity. b) Fine
64 quartzose-calcareous sandstones (LA3) from the Ørn Formation interval of the well 7128/4-1 (1814m).
65 The carbonate content is characterized by skeletal fragments (up to 30 %) and in minor amount by
66 blocky calcitic spar. The microfacies shows a high interparticle porosity. c-d) Bioclastic wackestone-
67 packstones (LA4) from the Ørn Formation interval of the well 7128/4-1 (1815m and 1842m
68 respectively) showing calcareous algae (*Epistomora sp.*, E), benthic foraminifera (F) encrustations of
69 bryozoans (B), *Tubiphytes* (T) and possible *Girvanella* (G). No visible porosity e) Bioclastic grainstones

70 (LA5) from the Ørn Formation interval of the well 7128/4-1 (1865m) dominated by globivalvulinid
71 foraminifera (Gv) and peloids, plus undifferentiated recrystallized skeletal fragments and encrusting
72 forms. f) Bioclastic grainstones (LA5) from the well 7128/6-1 (1837.75m) dominated by red algae
73 (*Komia* sp.) (K), bryozoan fragments and peloids. Note also the well developed interparticle-moldic
74 porosity. g) Rugose coral boundstones (LA6b) from the Ørn Formation interval of the well 7128/4-1
75 (1849.25m). The picture shows a micropeloidal matrix (m) and different generations of calcitic (c) and
76 anhydrite (a) cements, partially filling intergranular, intragranular and moldic/vuggy pores. Note the
77 high intraparticle porosity within the corallites. h) Bioclastic packstones (with dolomitized matrix)
78 occupying the interstitial space of the coral boundstones (LA6b), from the Ørn Formation interval of the
79 well 7128/4-1 (1849.25m). It shows coral and crinoid fragments plus others undifferentiated skeletal
80 components, often encrusted by *Girvanella* (G); *Tetrataxis* (Tx) and *Tuberitina* (t) foraminifera can be
81 recognized. Note also the high interparticle-moldic porosity.

82

83 **Figure 7.** Thin sections photographs of the most representative lithofacies associations (LA).

84 a-b) *Palaeoaplysina* boundstones (a) (LA6a) and interstitial matrix (b) (LA4) from the Ørn Formation
85 interval of the well 7128/4-1 (1818 m). The thallus morphology of *Palaeoaplysina* shows the typical
86 protuberances (p) and the upward-branching tubes (t) of the canal system mostly filled by the interstitial
87 matrix. The latter is made by bioclastic packstones from LA4, showing small benthic foraminifera (F),
88 fine fragments cystoporida bryozoans (B), ostracods (O) and possible *Tubiphytes* (T), plus
89 undifferentiated recrystallized skeletal grains.

90 c-d) Foraminiferal packstones (LA7) from the Ørn Formation interval of the well 7128/4-1 (1837m).
91 The microfacies is dominated by fusulinid foraminifera (F), with fragments of crinoids (C) and *Rugose*
92 corals (R), less small benthic foraminifera. In photo (d) the microfacies reflects a probable more distal

93 position. It shows scattered fusulinids (F) and *Tetrataxis* (Tx) foraminifera, crinoid (C) and trilobite (Tr)
94 fragments, plus other undifferentiated shells. The matrix is partially dolomitized, including common
95 sparse quartz grains (Ørn Formation interval of the well 7128/4-1, 1864 m).

96 e) Crinoidal-bryozoan grainstones (LA8) from the Ørn Formation interval of the well 7128/4-1 (1824m).
97 The microfacies is dominated by fragments of crinoids (C) and bryozoans (B). It shows moderate
98 interparticle-intraparticle porosity when pores are not occluded by syntaxial overgrowth of calcitic
99 cement.

100 f) Crinoidal-bryozoan grainstones (LA8) from the Isbjørn Formation interval of the well 7128/6-1
101 (1809.75m). It is characterized by fragments of crinoids (C), bryozoans (B) and *Tubiphytes* (T). The
102 microfacies is very similar to the one observed within the Ørn Formation (photo e) but in this case, as
103 for the whole the Isbjørn Formation interval studied, the porosity is very low, due to complete occlusion
104 by syntaxial and blocky cements.

105 g-h) Crinoidal-bryozoan silty wackestone-packstones (LA9) from the Ørn Formation interval of the well
106 7128/4-1 (1825 m). The microfacies shows chaotically arranged fragments of crinoids (C) and
107 bryozoans (B) in a calcisiltitic matrix with abundant quartz grains. In the more distal wackestones (photo
108 h) the grain-size decreases and the amount of matrix increase.

109

110 **Figure 8.** Schematic depositional models derived from the Asselian-Artinskian intervals of the wells
111 7128/6-1 and 7128/4-1, during the deposition of (a) the Ørn Formation (Gipsdalen Gp) and (b) the
112 Isbjørn Formation (Bjarmeland Gp). The models show the interpreted platform sub-environments, the
113 spatial distribution of the Lithofacies Associations (LA1-LA9) the relative abundance of the major
114 skeletal components across the platform profile and water masses circulation according with the shift in

115 carbonate sedimentation modes, driven by major changes in the palaeoceanographic/palaeoclimatic
116 conditions (see text for explanation). See figure 4 for the color code of the LA.

117 **Figure 9.** a) Gzhelian-Asselian large-scale facies map showing the limit of the subtidal evaporites of the
118 Nordkapp Basin (sulphatic evaporites and halite sequences cored from the wells 7228/9-1 S and
119 7229/11-1). The southern limit (contour in green) marks the approximate position of the palaeo-margin
120 at the Finnmark Platform/Nordkapp Basin transition. B) Sakmarian–Artinskian large scale facies map of
121 the Finnmark domain showing the seismically-interpreted large-scale distribution of the Sakmarian-
122 Artinskian stacked heterozoan buildup complexes. Modified after Gudlaugsson et al. (1998).

123 **Figure 10.** Seismic interpretation of the 2D line ST9715-213. a) Large scale view of the seismic line
124 across the SE-NW profile of the eastern Finnmark Platform and the seismic intervals corresponding to
125 the entire Gipsdalen Gp and Bjarmeland Gp. The line covers approximately 97 km in length. b) Seismic
126 profile showing the five selected horizons discussed in the text (in yellow) and the top Permian horizon
127 (in white), across the marginal platform area. c) Interpreted seismic profile derived from b, showing the
128 evolution of the marginal part of the Finnmark platform across the Gipsdalen and Bjarmeland Gp
129 transition. Note the change in geometries of the reflectors/margin, interpreted as associated to a change
130 from a distally steepened ramp (Ørn Formation) to homoclinal ramp (Bjarmeland Gp) profile. See text
131 for the detailed discussion.

late Sakmarian - late Artinskian Isbjørn Fm (Bjarmeland Group)

- Temperate latitudinal belt.
- Low ampl./frequency sea-level fluctuations.
- Poor stratified sea-water column and open circulation across the platform.
- Enhanced upwelling of cooler waters and trophism.
- Bryonoderm sedimentation mode.

Legend

- Continentally-influenced inner ramp
- Storm-dominated inner-middle ramp
- Offshore domain

Late Gzhelian-Early Sakmarian Ørn Fm (Gipsdalen Group)

- (Sub)tropical latitudinal belt.
- Glacio-eustatic influence with cyclic meteoric exposure of proximal domains.
- Stratified water column (stable thermocline) with warm superficial waters and cooler mid to outer shelf domains.
- Depth-related shift from Chloroform to Bryonoderm sedimentation mode.

Legend

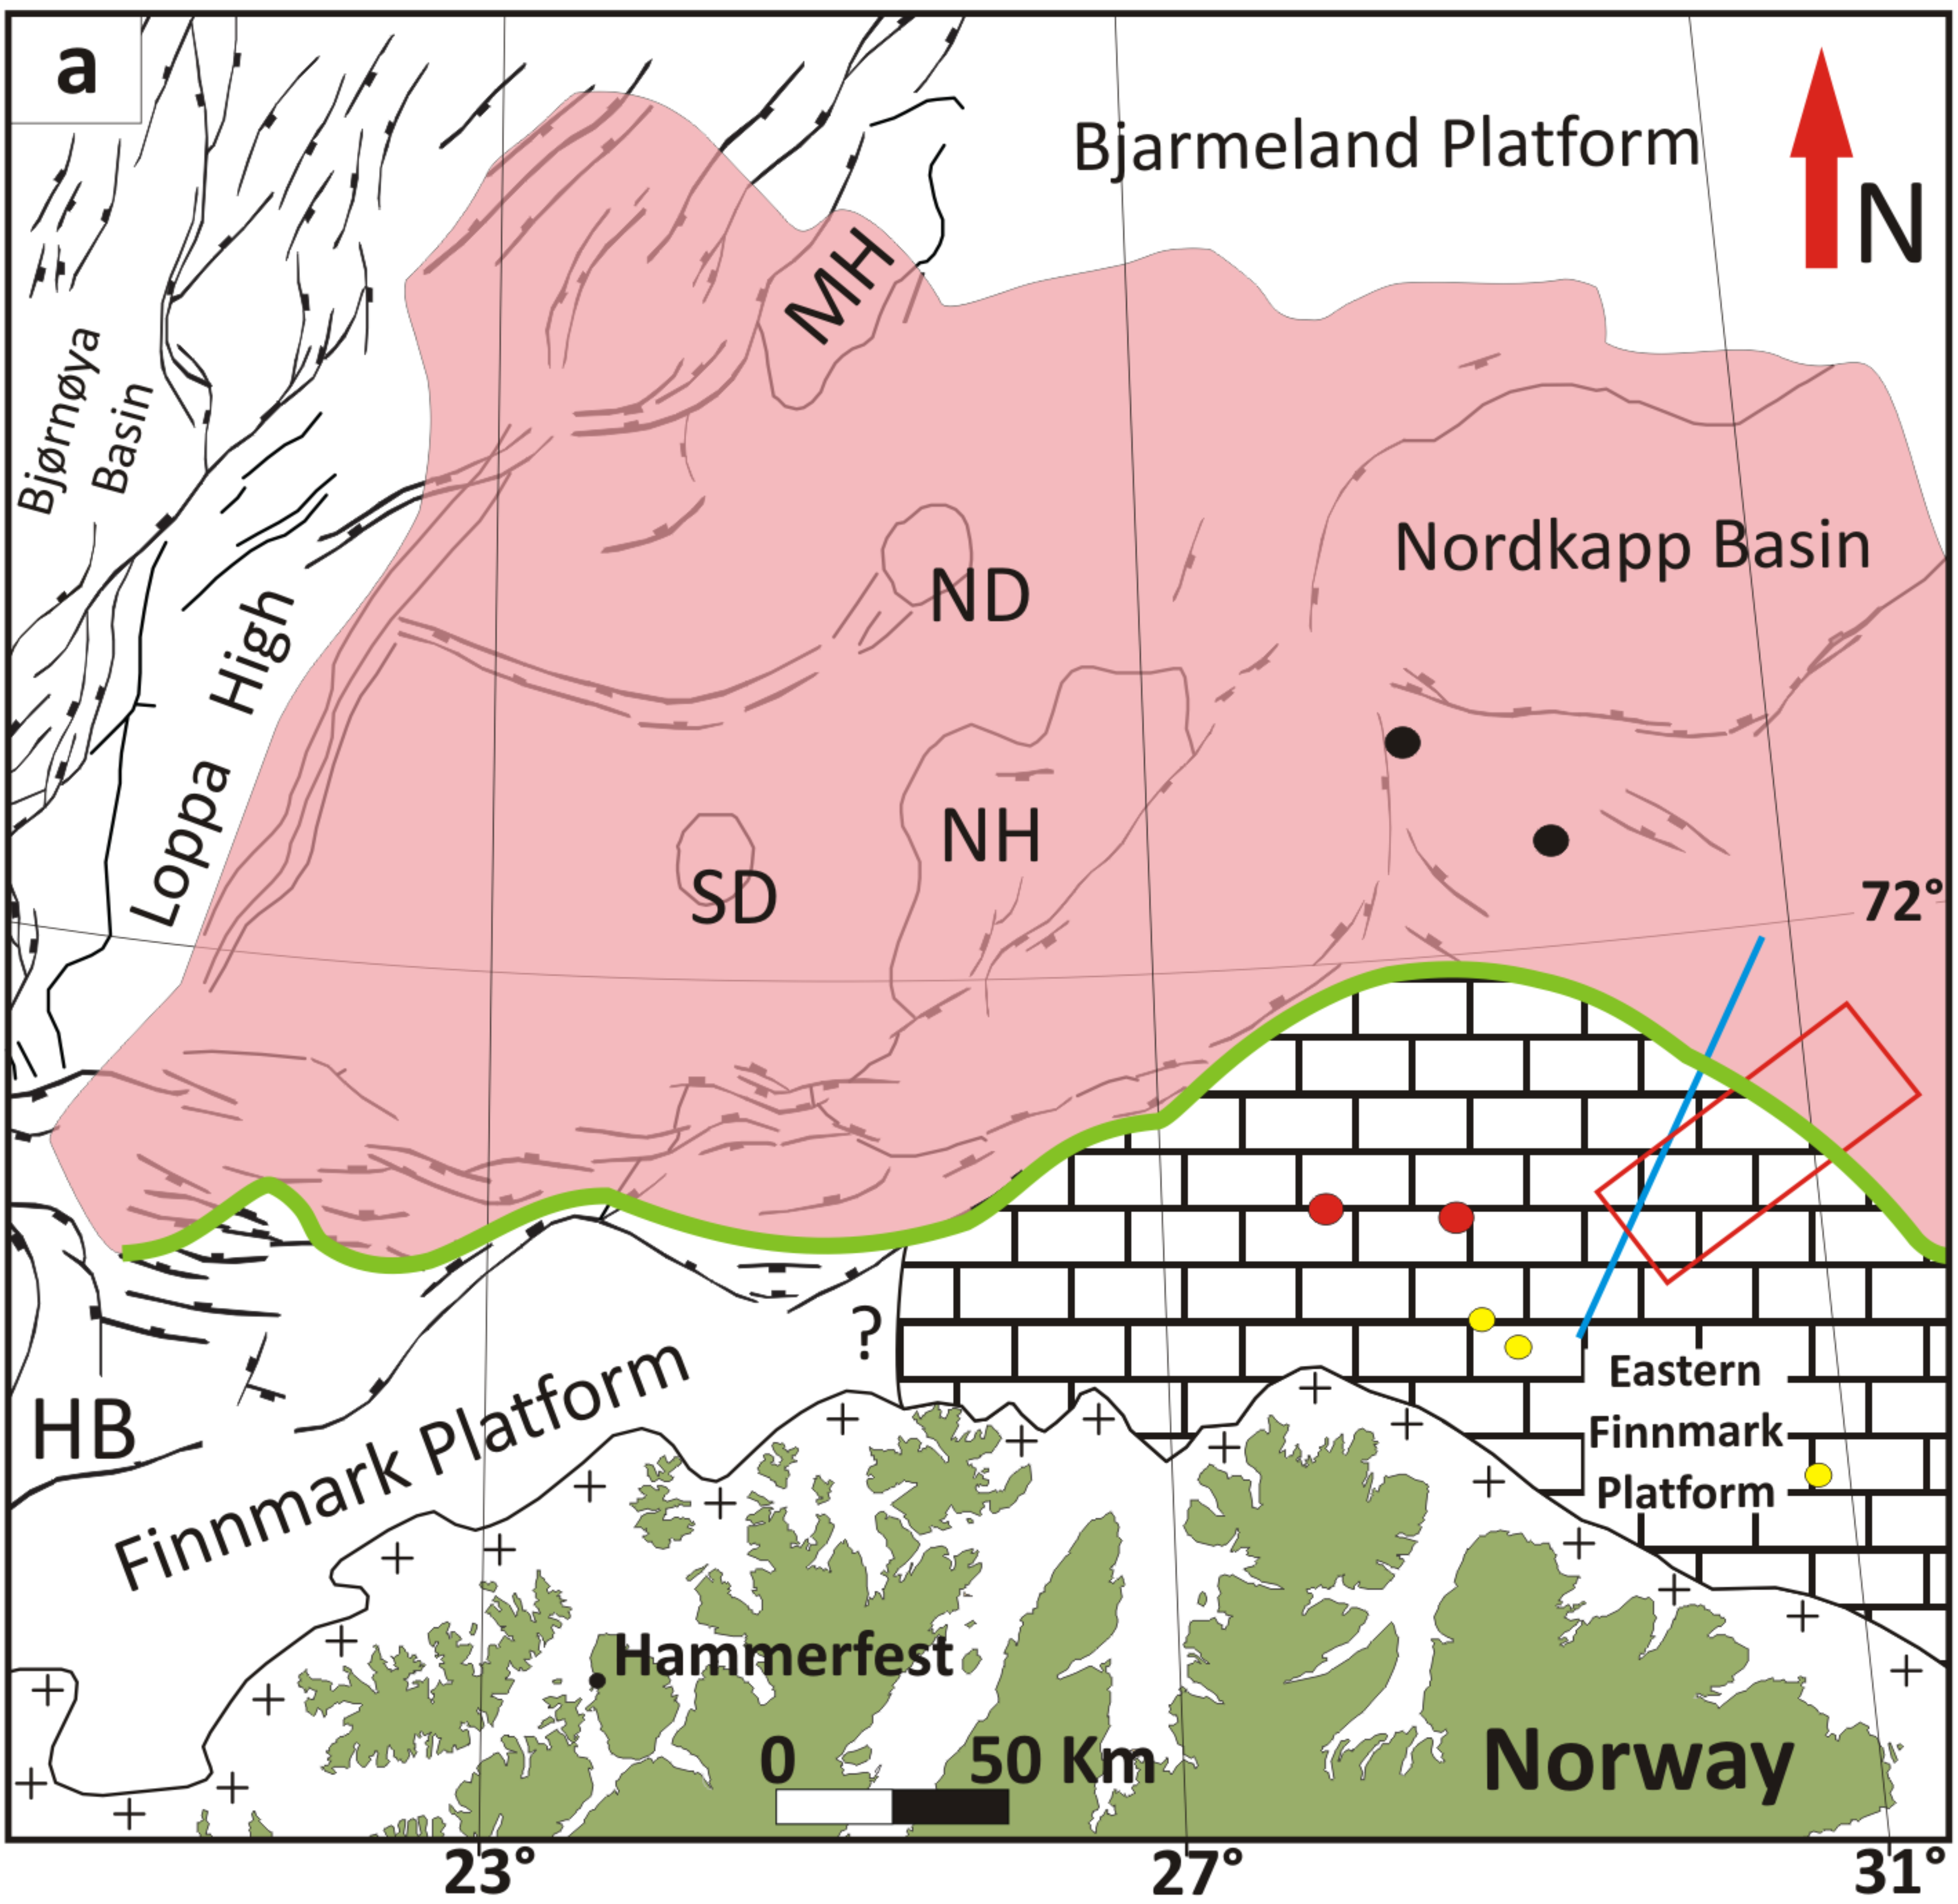

- Supratidal sabhka
- Restricted tidal flat/shallow lagoon
- Skeletal banks/shoals
- Partially protected shallow lagoon
- Open subtidal
